

## Search for the $1/2^-_2$ intruder bandhead in $^{35}\text{P}$

Nuclei in the  $N=20$  island of inversion, located around the neutron-rich  $^{32}\text{Mg}$  isotope, have ground-states dominated by deformed and collective configurations arising from neutron-pair excitations across the shell gap (See Ref. [1] for a recent review). Particle-hole sd-pf cross-shell intruder configurations have also been observed in the low-lying level scheme of heavier  $N = 20$  even-even nuclei. However, the expected  $1/2^-_2$  intruder bandhead has not yet been identified in the odd-even nucleus  $^{35}\text{P}$ . Previous attempts to identify this state suffered from a large background in the region of interest arising from contaminants in the target [2].

We will report on a recent measurement using the  $^{36}\text{S}(d, ^3\text{He})^{35}\text{P}$  reaction in inverse kinematics with the Helical Orbit Spectrometer (HELIOS) at ATLAS/ANL [3]. Thanks to the unique capabilities of HELIOS, enhanced with a recoil detector setup, it is possible to perform the reaction in nearly background free conditions.

An analysis of the reconstructed  $^3\text{He}$  spectrum in HELIOS did not show a peak that could be associated with the  $1/2^-_2$  intruder state. We have not observed any candidate state in the region of interest with an intensity greater than 5% of the ground-state. This in turn can be used to set a limit to the amount of  $2p2h$  excitations in the  $^{36}\text{S}$  ground state wavefunction. These results provide an additional constraint to state-of-the-art theoretical descriptions to further understand the evolution of shell structure in the region.
